Supporting Information

ABSTRACT: The resolving power of differential ion mobility spectrometry (FAIMS) was dramatically increased recently by carrier gases comprising up to 75% He or various vapors, enabling many new applications. However, the need for resolution of complex mixtures is virtually open-ended and many topical analyses demand yet finer separations. Also, the resolving power gains are often at the expense of speed, in particular making high-resolution FAIMS poorly compatible with online liquid-phase separations. Here, we report FAIMS employing hydrogen, specifically in mixtures with N₂ containing up to 90% H₂. Such compositions raise the mobilities of all ions and thus the resolving power beyond that previously feasible, while avoiding the electrical breakdown inevitable in He-rich mixtures. The increases in resolving power and ensuing peak resolution are especially significant at H₂ fractions above ~50%. Higher resolution can be exchanged for acceleration of the analyses by up to ~4 times. For more mobile species such as multiply charged peptides, this exchange is presently forced by the constraints of existing FAIMS devices, but future designs optimized for H₂ should consistently improve resolution for all analytes.

Ion mobility spectrometry (IMS) comprises¹⁻³ methods for separating, characterizing, or identifying ions based on their transport through gases driven by an electric field (E). The role of IMS coupled to mass spectrometry (MS) in analytical science had steadily risen over the past decade, as IMS/MS has grown from a niche technique for structural elucidation of exotic clusters to a alternative or complement to condensed-phase approaches of liquid chromatography (LC) or electrophoresis for rapid bioanalytical separations.⁴ In parallel with the emergence of new applications, IMS capabilities have been expanded through introduction of novel methods and commercial instrumentation exploiting them. Of note is the development of differential or field asymmetric waveform IMS (FAIMS)⁵⁻³ based not on the absolute ion mobilities (κ) employed by conventional IMS (whether drift tube¹ or traveling wave⁶ IMS) but the difference of κ between low and high E.

That difference is measured in FAIMS directly, by subjecting ions to a dynamic field in a gap between two electrodes, established using a periodic asymmetric waveform of some peak amplitude (termed “dispersion voltage”, DV). Ions injected into the gap oscillate and migrate to one of the electrodes because of different mobilities during opposite-polarity segments with unequal E. For a species with a given difference between those κ values, the net migration can be offset using a weak time-independent “compensation field” (E_C) superposed on the separating field. Scanning E_C reveals the spectrum of species present. Performance strongly depends on the gap shape. Global metrics of FAIMS separation power are the resolving power (R), the κ value for a peak divided by its full width at half-maximum (w), and peak capacity (p), the separation space for a given analyte set divided by w. The metric for specific analytes is resolution (r), the κ difference between two peaks divided by w. An inhomogeneous field in curved (cylindrical or spherical) gaps permits equilibrating multiple species simultaneously, which broadens the peaks. Therefore, all three metrics are maximized with planar gaps, where the field is homogeneous and only one species can be in perfect equilibrium at any time.⁶⁻⁷ For example, planar units have provided R ~ 40–70 for multiply charged peptide ions vs ~6–12 in a commercial device with a cylindrical gap of equal 2 mm width (using the same DV = 4 kV, 1:1 He/N₂ gas mixture, and “standard” filtering time of t = 0.2 s).⁸

Another factor in IMS is the buffer (carrier) gas identity. The mobility at low E depends on the masses of the ion (m) and gas molecule (M), and the ion—molecule collision integral or cross section (Ω) by the Mason-Schamp equation:²

$$K = \frac{3}{16} \frac{2\pi (m + M)}{mMKT} ^{1/2} ze NΩ$$  \hspace{1cm} (1)

where k is the Boltzmann constant, ze is the ion charge, and T and N are the gas temperature and number density. Ions of interest are normally much larger and heavier than the common gas molecules (He, N₂, or CO₂), and Ω is primarily controlled by ion size and shape, whereas the reduced mass nearly equals M. Thus varying the gas composition generally scales the mobilities of all ions similarly and hence affects conventional IMS separations only marginally, if at all.⁹⁻¹⁰ The resolving power is independent of gas identity:¹

$$R = \frac{1}{16m^2} \left( \frac{Uze}{kT} \right) ^{1/2}$$  \hspace{1cm} (2)

The small variation of separation properties and no variation of $R$ mean virtually no effect on the peak capacity; indeed, that for protein tryptic digests is essentially independent of the gas (He, CH$_4$, N$_2$, or Ar). The relative peak positions for smaller ions such as iodo-, bromo-, and chloro-anilines (128–220 Da), arginine and phenylalanine (166 and 175 Da), or lorazepam and diazepam (284 and 302 Da) may be shifted and even inverted, by switching between gases with differing molecular polarizabilities ($\alpha$: He (0.20 Å$^3$), Ar (1.64 Å$^3$), N$_2$ (1.74 Å$^3$), and CO$_2$ (2.91 Å$^3$)). This may be useful for targeted separations, but not broad analyses as the peak capacity remains unchanged. Such shifts are not observed for medium-size ions (e.g., tetrapeptides) or larger species, for which $\Omega$ is primarily dictated by ion properties as stated above. Thus, conventional IMS has largely utilized convenient and inexpensive N$_2$ or (air) or He that permits simpler and more accurate $a$ priori mobility calculations and thus is preferred for structural determination.

In contrast, the $K(E)$ derivative that underlies FAIMS is governed by the details of ion–gas molecule interaction potential that are sensitive to the physical and chemical properties of the molecule. Hence modifying the gas composition may sharply affect separations; even the $E_C$ sign may be inverted by switching from CO$_2$ or N$_2$O to O$_2$, N$_2$, or SF$_6$. Small amounts of moisture or organic (e.g., alcohol) vapors in the gas may not only change species peak order but greatly increase $E_C$ values, expanding the separation space and peak capacity. For example, the maximum resolving power for phthalic acid isomers (ortho, meta, and para) can be raised nearly 5-fold (from 27 to 140) by adding 1.5% methanol vapor to N$_2$. This is caused by reversible clustering, where vapor molecules adsorb on an ion during the weak-field segment of the waveform (when the ion temperature $T_i$ is low) and evaporate in the “warmer” strong-field segment (as field heating elevates $T_i$). This process may drastically decrease $K$ at low (but not high) $E$, creating much steeper $K(E)$ curves and thus wider separation spaces than feasible in true gases. This approach has had success for smaller 1+ ions such as amino acids and dipeptides, but so far not for larger and particularly multiply charged species such as proteolytic peptides (ordinarily with ~5–25 residues) and proteins generated by electrospray ionization (ESI) and relevant to proteomics. At least in part this is due to a facile charge reduction of multiply charged ions by exothermic proton transfer to vapor molecules or clusters with higher proton affinities.

Alternatively, the separation power of FAIMS with any gap shape is generally improved when He is added to heavier gases, such as N$_2$, CO$_2$, or SF$_6$. First, in planar devices at moderate $E$, the peak widths scale as $K^{-1/2}$. This scaling is not exact, mostly because the anisotropy of ion diffusion at high $E$ breaks the linear dependence of the diffusion coefficient ($D$) on mobility, but is a fair approximation for “full-size” (not miniatuized) analyzers. Hence making ions more mobile narrows the peaks and improves all separation power metrics that are proportional to $1/w$. As noted above, the $K$ values for reasonably large ions in the low-$E$ limit scale as $1/(\Omega M^{1/2})$. This approximately applies in FAIMS, as the mobilities of these ions at moderate $E$ deviate from $K(0)$ only marginally. Thus, the mobilities for larger ions with equal $\Omega$ in He ($M = 4$ Da) exceed those in N$_2$ ($M = 28$ Da) by $\sim 7/2 = 2.65$ times. Ions also have lower cross sections with He atoms than the larger and more polarizable N$_2$ molecules. This factor increases the ratio of mobilities in He and N$_2$ by $\sim 10$–50% (more so for smaller ions where the collision partner identity is more important), and typical biomolecular ions are more mobile in He by $\sim 3$–4 times than in N$_2$. By Blance’s law, the mobilities in He/N$_2$ then exceed those in N$_2$ by $\sim 1.5$–1.6 and $\sim 2$–2.3 times at 50% and 75% He, respectively. (Although the “law” is not accurate at higher fields, it suffices for such estimates.) The FAIMS peaks narrow accordingly, contributing about half to the resolution gains upon He addition. The other half comes from expanding separation space due to (1) stronger $K(E)$ dependences in He compared to N$_2$ and (2) non-Blanc phenomena that tend to magnify those dependences in mixtures of molecules that form dissimilar potentials with ions, such as such as He and N$_2$.

However, He promotes electrical breakdown, and its threshold drops with increasing He content. This drawback limits the He fraction in usable mixtures, for He/N$_2$ to $\sim 50$–75% (depending on the peak $E$), although higher fractions tend to improve separations. Increasing the He content from zero to the maximum raises $R$ of planar FAIMS devices for multiply charged peptides by $\sim 5$–10 times (from $\sim 10$–40 to $\sim 100$–220 in $t = 0.2$ s) opening new applications such as routine separation of sequence and localization isomers. The gains for smaller ions are similar in particular enabling resolution of isotopologues.

Close to the threshold, breakdown across the gap may be triggered by minor variations of DV output, ambient gas pressure, temperature, or composition, and/or changes of nature or quantity of ions in the gap during $E_C$ scan or due to source intensity fluctuations. Such breakdown causes analysis failure, sample loss, downtime for system cleaning and recalibration, and can also damage equipment and impede automation by necessitating close operator oversight. Stable operation requires tight control of all relevant parameters and tolerance of the waveform generator to shorting across the load should breakdown occur. Many existing systems, including those with active feedback loops for DV control in some current products, do not withstand such shorting and must be operated well below the breakdown threshold despite the diminished performance.

Another factor is helium cost, projected to increase in the near future. The flow rate of carrier gas to typical FAIMS devices ($Q$) is $\sim 2$–4 L/min, and the cost of consumed He significantly impedes the acceptance of FAIMS, particularly outside of the U.S. where He is more expensive and harder to procure. Unfortunately, use of just N$_2$ has so far not produced the high resolution provided by He/N$_2$ mixtures and needed for advanced separations.

As usual for separations in media, FAIMS resolving power scales as $t^{1/2}$. This is rigorous in the infinite $t$ limit, where the time for onset of filtering (required for ions migrating toward electrodes to fill a finite gap) is negligible in comparison, and a good approximation with the long filtering times needed for high resolution. Thus, even higher $R$ (up to $\sim 330$ for multiply charged peptides) were reached by extending $t$ from 0.2 s to 0.8 s. However, the minimum time for an $E_C$ scan is $\sim 2pt$, accounting for downtime while ions exit the gap once $E_C$ is incremented. This situation renders even $t = 0.2$ s too long for many applications, crucially LC/FAIMS/MS without slowing the LC gradient or sacrificing the peak capacity through selective $E_C$ stepping. For example, a scan with $p \sim 130$ for tryptic digests (provided by maximum $R \sim 200$) takes at least $\sim 1$ min, which substantially exceeds the eluting peak widths in modern HPLC. Raising the resolving power by extending $t$ augments the problem as both $p$ and $t$ increase. For instance,
a scan with $p \approx 200$ achievable in $t = 0.5$ s takes at least $\sim 3$ min or $>10$ times the peak widths in practical HPLC.

Desiring to improve the FAIMS resolution and throughput without compromising the other and to increase both from present levels, we explored a buffer using hydrogen, specifically in $\text{H}_2/\text{N}_2$ mixtures. This medium provides resolving power and resolution matching or exceeding that achieved in $\text{He}/\text{N}_2$, while substantially accelerating analyses.

## EXPERIMENTAL METHODS

We used a planar FAIMS unit coupled to a modified LTQ ion trap mass spectrometer (Thermo Fisher).\textsuperscript{23–26} The $\text{H}_2/\text{N}_2$ gas with the $\text{H}_2$ fraction ($\nu/\nu$) of $0–100\%$ was formulated by flow meters (MKS Instruments, Andover, MA) and supplied at $Q = 1.0–2.7$ L/min. This value was limited by the highest $\text{H}_2$ inflow permitted by present MS pumping capacity. The calculated ion residence time in the gap, which is proportional to $1/Q$, was $t = 0.40–0.15$ s. As with $\text{He}/\text{N}_2$ mixtures, the samples were infused at $\sim 0.5 \mu\text{L}/\text{min}$. Performance was evaluated using reserpine and selected peptides, dissolved to $\sim 10 \mu\text{M}$ in our previously adopted ESI infusion solvent (50/49/1 water/methanol/acetic acid).

Flammability of $\text{H}_2$ requires safety precautions, and the major concern is $\text{H}_2$ expelled into the lab. While some carrier gas is evacuated through the MS system into the pumping exhaust, most enters the lab from the FAIMS inlet and the unsealed FAIMS/MS interface (especially at elevated $Q$ values). In a small and/or poorly ventilated space, the $\text{H}_2$ inflow can accumulate and cause fire or explosion, conceivably triggered by a spark in the unit. Hence the instrument was installed in a spacious, thoroughly ventilated laboratory where even continuous operation at maximum $\text{H}_2$ flow could not build up dangerous $\text{H}_2$ concentrations. The risk of leaks from the line taking $\text{H}_2$ from its source to the unit was mitigated by placing the $\text{H}_2$ cylinder in a ventilated cabinet and connecting it to the unit using steel (rather than common plastic) tubes with Swagelok fittings. The local $\text{H}_2$ concentrations near the ESI/FAIMS and FAIMS/MS junctions can still be high, and a discharge between the ESI emitter and curtain plate (cp) of the FAIMS device can ignite the gas coming out of the cp orifice. Thus, at the higher $\text{H}_2$ fractions, we have decreased the cp voltage from the usual $1 \sim 0.7$ kV, reduced the offset of ESI emitter over cp from $\sim 2.4$ to $\sim 1.6$ kV, and increased the distance from the emitter tip to cp.

The turbomolecular pumps of LTQ MS lose efficiency when evacuating $\text{He}$ and even more so for $\text{H}_2$. With $Q = 2$ L/min, the pressures measured by the ion and convection gauges increase from, respectively, $1 \times 10^{-5}$ and 1.3 Torr in $\text{N}_2$, to $2.4 \times 10^{-5}$ and $\sim 9$ Torr at $>70\% \text{H}_2$. While we operated in that regime for hours, it is far above the normal pressure range for this and other common commercial API/MS platforms that are not designed to aspirate $\text{H}_2$-rich mixtures from the inlet. Elevated pressure in the MS manifold may affect the accuracy, resolution, and/or sensitivity of MS analyses and cause hardware failures. The present MS system shuts down when the convection gauge measures $>10$ Torr, precluding $Q$ above $\sim 2.5$ L/min for $\text{H}_2$-rich mixtures.

## FUNDAMENTALS OF RESOLVING POWER FOR FAIMS EMPLOYING HYDROGEN

Hydrogen improves FAIMS resolution for the same reasons as $\text{He}$. The key advantage of $\text{H}_2$ are breakdown thresholds that greatly exceed those for $\text{He}$, e.g., $\sim 4.5$ kV vs $\sim 1$ kV for a dc voltage over a 2 mm gap at atmospheric pressure and temperature.\textsuperscript{33} The values for high-frequency rf voltages are slightly greater, and our device with a $1.88$ mm gap sustains up to $100\%$ $\text{H}_2$ at $D_V = 4.6$ kV and $\sim 92\%$ $\text{H}_2$ (versus $\sim 50\%$ $\text{He}$ in $\text{He}/\text{N}_2$) at the maximum $D_V = 5.4$ kV, the highest ever reported.\textsuperscript{7,24} Given that $\text{N}_2$, CO$_2$, or SF$_6$ resist breakdown better than $\text{H}_2$ nearly all mixtures of $\text{H}_2$ with those gases can be employed without breakdown.

As $\text{H}_2$ molecules ($M = 2$ Da) have half the mass of $\text{He}$, the mobilities of large ions with the same $Q$ in $\text{H}_2$ are $2^{1/2} = 1.41$ times those in $\text{He}$. While early fundamental studies of the mobilities for the smallest ions included $\text{H}_2$ and its mixtures,\textsuperscript{38–41} analytical IMS has not and no cross sections of larger ions with $\text{H}_2$ have been measured. These should somewhat exceed $Q$ with $\text{He}$ because diatomic $\text{H}_2$ is larger and more polarizable ($\alpha = 0.82 \text{Å}^3$), resulting in deeper ion–molecule potentials. However, $\text{H}_2$ is smaller and less polarizable than $\text{N}_2$, meaning shallower potentials and smaller $Q$ values. Thus, the difference of $Q$ between $\text{He}$ and $\text{H}_2$ should be less than the $\sim 1.1–1.5$ times between $\text{He}$ and $\text{N}_2$, and mobilities in $\text{H}_2$ are likely greater than those in $\text{He}$, at least for relevant larger ions where $Q$ depends on the gas only weakly. Hence the peaks for such ions in FAIMS using $\text{H}_2/\text{N}_2$ mixtures should be slightly (up to $\sim 15\%$) narrower than those in $\text{He}/\text{N}_2$ with the same $\text{N}_2$ fractions.

Much more important is the ability to operate at up to $\sim 100\%$ $\text{H}_2$ impossible with $\text{He}$ as we discussed. For the same $Q$, the mobilities in $\text{H}_2$ exceed those in $\text{N}_2$ by $14^{1/2} = 3.74$ times, as opposed to the (Blanc-law) factor of $1.45$ in $\text{He}/\text{N}_2$ with a maximum of $50\%$ He at $D_V = 5.4$ kV. Considering the smaller cross sections in $\text{H}_2$ than in $\text{N}_2$, the mobilities in $\text{H}_2$ should be $\sim 4–5$ times those in $\text{N}_2$ vs the said $1.5–1.6$ times in $1:1 \text{He}/\text{N}_2$. Thus, substituting $\text{H}_2$ for $\text{He}$ in mixtures with $\text{N}_2$ should increase $K$ values by up to $\sim 2.7–3.1$ times, further narrowing the spectral peaks by $\sim 1.6–1.8$ times. With $90\%$ $\text{H}_2$ workable at the maximum $D_V$ here, the calculated mobilities are somewhat smaller at $\sim 3–4$ times those in $\text{N}_2$ and $\sim 2–2.5$ times those in $1:1 \text{He}/\text{N}_2$ hence the peak narrowing relative to the latter would be a lesser $\sim 1.4–1.6$ times.

As we mentioned, $R$ and $p$ are proportional to $E_C$ and separation space, respectively. Experiments for representative analytes (below) prove that $E_C$ values and thus separation space widths in $\text{He}/\text{N}_2$ and $\text{H}_2/\text{N}_2$ are close for $\text{He}$ or $\text{H}_2$ concentrations up to $50\%$. However, as the $\text{H}_2$ fraction goes to $100\%$, the $E_C$ values far exceed those for $\text{He}/\text{N}_2$ with $50\% \text{He}$, adding to the advantage of narrower peaks. As a result, much higher FAIMS resolving power can be attained in equal time using $\text{H}_2/\text{N}_2$ than $\text{He}/\text{N}_2$ compositions.

Ion beams in gases are broadened by diffusion and space-charge expansion due to Coulomb repulsion.\textsuperscript{42} The former is independent of the ion density $\sigma$, while the latter scales as $\sigma^3$. The $\sigma$ value in FAIMS is limited by Coulomb expansion eliminating excess ions, thus diffusion dominates.\textsuperscript{43} For optimum performance, the effective gap width $g_e$ in a FAIMS device (mechanical width $g$ less the amplitude of ion oscillations in the waveform cycle $d$) must compare with the beam broadening during filtering time $t$. As $D$ and $K$ values are approximately proportional at moderate $E$, the beams spread in $\text{H}_2$ much faster than in $\text{N}_2$ or permissible $\text{He}/\text{N}_2$ mixtures, by $\sim 3$ times relative to $1:1 \text{He}/\text{N}_2$ based on the mobilities estimated above (and actually more because of enhanced field heating of the ions). The value of $d$ is proportional to mobility and thus is scaled by the same factor. For many polyatomic ions with $K \sim 1–2$ cm$^3$/(V·s) in $\text{N}_2$, this
means going from $d \sim 0.15-0.3$ mm in 1:1 He/N$_2$ to $d \sim 0.4-1$ mm in H$_2$. For the present 2:1 bisinusoidal waveform with DV = 5.4 kV and 750 kHz frequency. With unchanged $q \sim 2$ mm, nearly all ions for species with $K > \sim 1.2$ cm$^2$/V s are non-selectively destroyed on electrodes over the typical $t = 0.2$ s. This limits the H$_2$/N$_2$ mixtures in that regime to $\sim 55-80$% H$_2$ for many analytes, which caps the resolution gains provided by H$_2$ in existing devices not designed for such buffers. With the diffusion broadening scaling as $(Dt)^{1/2}$, the $g_c$ value suitable for 1:1 He/N$_2$ gas has to be raised by at least $\sim 60-80$% for H$_2$, e.g., from the present $\sim 1.6-1.7$ mm to $\sim 2.6-3.1$ mm. This increase translates into an increase of physical width from $\sim 1.9$ mm to $\sim 3.2-3.8$ mm (at least). Then, for constant $E$, one has to scale DV in proportion, i.e., from 5.4 kV to $\sim 9-11$ kV.

A FAIMS unit with a 2 mm gap in principle, can utilize higher H$_2$ fractions with faster separations. For the same ion transmission efficiency, one would have to decrease $t$ by a factor of $1/D$ (or $\sim 3$ times as estimated above for H$_2$ versus 1:1 He/N$_2$) had the oscillation amplitude remained constant. The greater $d$ value computed above decreases the effective gap width by $\sim 15-40$% (from $\sim 1.6-1.7$ mm in 1:1 He/N$_2$ to $\sim 0.9-1.5$ mm in H$_2$).

To compensate, $t$ is to be shortened by further $\sim 1.4-3$ times (or $\sim 4-10$ times total), i.e., from 0.2 s to 20-50 ms. This would be achieved by increasing the rate of gas flow to the device, presently from $Q = 2$ L/min (for $t = 0.2$ s) to $\sim 8-20$ L/min. However, the pumping constraints (Experimental Methods) have precluded $Q > 2.4-2.7$ L/min at high H$_2$ fractions. According to the above square-root scaling, the consequent reduction of $t$ by $\sim 1.2-1.35$ times (to 0.15–0.17 s) broadens the peaks by $\sim 10-15$% less than the benefit of higher ion mobilities that we estimated as $\sim 1.6-1.8$ times for H$_2$ and $\sim 1.4-1.6$ times for 9:1 H$_2$/N$_2$. Hence both higher resolution and faster separation are achievable. With that, we move to the experimental evaluation for representative analytes.

## DEMONSTRATION OF FAIMS ANALYSES IN HYDROGEN

A widely used standard in IMS and FAIMS is reserpine, which commonly contains 3,4-dehydroreserpine due to oxidative dehydrogenation. In positive-mode ESI, these produce 1+ protonated ions with $m/z = 609$ and 607, respectively. As the H$_2$ fraction grows from 0 to 80%, the FAIMS resolution of these species in $t = 0.2$ s increases 9-fold (from $r = 1.1$ to 9.7) as the peaks narrow while the distance between them expands (Figure 1). Even higher $r = 15-16$ were reached at $80-88$% H$_2$ using $t = 0.27-0.4$ s, which is still shorter than 0.6 s needed for the maximum resolving power in He/N$_2$ mixtures. The $E_C$ values in H$_2$/N$_2$ mixtures are similar to those in He/N$_2$ up to 50% H$_2$ or He, but at the near-maximum 90% H$_2$ exceed the highest in He/N$_2$ (at 50% He) by 1.5 times (Figure 2a). The flattening of curve at $\sim 90$% H$_2$ portends the $E_C$ decrease at higher H$_2$ fractions, suggesting that those would not improve separation even if the electrical breakdown could be averted. As anticipated from calculations, the peaks measured using He/N$_2$ in $t = 0.2$ s are somewhat narrower than those using He/N$_2$ mixtures for equal $t$ and N$_2$ content (in the region of overlap), and the widths for $>50$% H$_2$ lie on the extrapolation of the trend up to 50% H$_2$ (Figure 2b). The values for $t > 0.2$ s adjusted to $t = 0.2$ s via multiplication by $(t/0.2)^{1/2}$ track the same trend, also in agreement with theory. With $t = 0.2$ s, the resolving power exceeds that using He/N$_2$ already at 50% H$_2$ (because of narrower peaks) and rapidly increases at higher H$_2$ fractions as $E_C$ values escalate, to 105 (or $>3$ times that in 1:1 He/N$_2$) at 85% H$_2$ (Figure 2c). The results at 85% H$_2$ and $t = 0.4$ s were verified by 20 replicates, yielding a mean $s = 0.755 \pm 0.031$ cm/s with 95% confidence (Figure S2 in the Supporting Information) and $R = 159 \pm 7$, which is 2.6 times that achieved$^{36}$ using 1:1 He/N$_2$ despite a longer $t = 0.6$ s. The value for dehydroreserpine is yet greater, $R = 176$. The resolution of different species improves in proportion (Figure 1). Such resolution gains despite faster separation evidence the potential for FAIMS in H$_2$-rich mixtures.

More topical are separations of peptides, especially isomers such as those derived from proteolytic digestion of isomeric proteins ubiquitous in biology. For sequence inversions where residues are transposed and localization variants where post-translational modifications (PTMs) are moved along the backbone. These isomers normally differ in biological activity but are often challenging to characterize by tandem MS using ergodic methods such as collision-induced dissociation (CID). This is the case for sequence isomers with basic amino acids or permuted N-terminal and next residues. Particularly difficult are inversions of modified peptides with “electron predator” PTMs such as nitrate, which are preferentially abstracted during CID and produce uninformative fragments upon electron capture or transfer dissociation (EC/TD). For localization variants, CID again causes PTM abstraction with uninformative fragments and PTM migration that yields misleading fragments, while EC/TD is inefficient and nonspecific, leading to low sensitivity. Mixtures of three or more variants cannot be characterized by MS/MS (either CID or EC/TD) because of the absence of unique fragments for at least one isomer. Separation of peptide isomers prior to MS is thus called for, yet known chromatographic approaches to that are slow, require extensive

Figure 1. Spectra for 1+ reserpine and 3,4-dehydroreserpine ions measured using DV = 5.4 kV in H$_2$/N$_2$ with 0–90% H$_2$ and filtering times as labeled. The peak resolution values are marked. Data for more H$_2$ fractions are shown in Figure S1 in the Supporting Information.
method development, and frequently do not deliver satisfactory resolution. Such species were recently separated using FAIMS with He/N₂ mixtures, and we evaluate the utility of H₂/N₂ for this application below.

The tryptic peptide nYAAAAAAK (782 Da), where nY is nitrotyrosine, has seven tryptic sequence isomers that were distinguished by FAIMS using He/N₂ mixtures (albeit not easily). For example, AAnYAAAAK (3) and AAAnYAAAK (4) were baseline-resolved as 1+ ions only at extended filtering times (at least 0.33 s), Figure 3. The resolutions of 3 and 4 obtained in He/N₂ with 40% He at t = 0.2 and 0.33 s are matched using H₂/N₂ with 40% and 60% H₂ respectively, at t = 0.2 s. In line with the results for reserpine, adding H₂ up to 88% about doubles the R and r values at a similar filtering time.

Proteome analyses commonly utilize ESI and related ion sources that tend to generate multiply protonated peptides, commonly with the charge state (z) of 2. Conformational, sequence, and localization isomers of peptides with z = 2–4 were separated by FAIMS in He/N₂ with resolving power and resolution generally superior to those for z = 1. Resolution of multiply charged peptides may be investigated using Syntide 2 (1508 Da) that produces abundant 2+, 3+, and 4+ ions in ESI and served as a benchmark in our FAIMS studies in He/N₂. The higher mobilities of 2+ and particularly 3+ and 4+ peptides bring about their faster elimination from the gap compared to 1+ peptides, effectively limiting the H₂ content for z = 3 and 4 to less than 90%, namely, ∼70% for z = 3 and ∼60% for z = 4. For the same reason, we could not employ extended t to maximize the resolving power for these peptides at higher H₂ fractions and actually had to use t < 0.2 s to measure the peak widths for z = 3 at ∼60% H₂.

At t = 0.2 s, the maximum E_C values (obtained at or near the highest possible H₂ fractions) exceed those in 1:1 He/N₂ for all z by ∼60% for z = 2 and ∼10–20% for z = 3 and 4 (Figure 4). The smaller increases for 3+ and particularly 4+ ions are consequent upon a lower maximum H₂ content, as the absolute E_C values would be higher at ∼85–90% H₂. In other aspects, the findings follow the trends for 1+ ions noted above: the peak widths in H₂/N₂ mixtures are slightly below those in He/N₂ with equal N₂ fractions up to the maximum He content (50%), then decrease along the same linear trends until t has to be reduced, and then stay roughly level. As a result, the maximum resolving powers at t = 0.2 s exceed those obtained using He/N₂ mixtures by ∼3 times (R ~ 200 vs ~70) for z = 2 and ∼30–40%
(R ~ 280–300 vs ~200–220) for z = 3 and 4 (Figure 4). These metrics were validated by replicate analyses (Figure S4 in the Supporting Information), yielding a mean \( w = 1.03 \pm 0.064 \text{ V/cm} \) and \( R = 185 \pm 12 \) for \( z = 2 \) using 84% \( \text{H}_2 \) and mean \( w = 0.818 \pm 0.060 \text{ V/cm} \) and \( R = 291 \pm 21 \) for \( z = 3 \) using only 50% \( \text{H}_2 \) (at 95% confidence). For \( z = 2 \), the maximum \( R \) achieved here is greater than \( \sim 130 \) reached\(^{36} \) in \( \text{He}/\text{N}_2 \) using the longest feasible \( t = 0.5 \text{ s} \). The diminishing benefit of \( \text{H}_2 \) substitution for higher peptide charge states at least partly results from increasing \( K \) values that preclude the highest \( \text{H}_2 \) fractions with the current restricted gaps. This is a limitation of the present device rather than the \( \text{H}_2/\text{N}_2 \) medium per se and can likely be remedied by widening the gap as specified above.

Gas-phase peptides commonly exhibit multiple conformers, some mirroring those in solution.\(^{51} \) Their separation and characterization is of interest for structural biology and investigations of protein misfolding disorders.\(^{52} \) To gauge the utility of hydrogen-based media for separating peptide conformers (in particular, multiply charged ones), we explored the 2+ ions of bisphosphorylated\(^{45} \) APLpSFRGSLPkpSYVK (1809 Da), Figure 5. As with Syntide 2, the \( E_C \) values increase upon \( \text{H}_2 \) addition, while peak widths decrease with fixed \( t \) and remain constant with reduced \( t \) at >80% \( \text{H}_2 \). These gains translate into better resolution, with the conformers a and b separated increasingly well. The spectrum at 70% \( \text{H}_2 \) resembles that in \( \text{He}/\text{N}_2 \) with the maximum \( \text{He} \) content,\(^{36} \) while those at 75–85% \( \text{H}_2 \) exhibit slightly better resolution despite a 4-fold acceleration of analysis. Using \( \text{He}/\text{N}_2 \), a and b could be only partly resolved in \( t = 0.2 \text{ s} \).\(^{36,45} \) Thus FAIMS in \( \text{H}_2 \)-rich mixtures allows faster filtering singly or multiply charged peptides with specificity close to or exceeding that in \( \text{He}/\text{N}_2 \). The relative separation of both primary and secondary structure isomers tracks that in \( \text{He}/\text{N}_2 \).

Increasing the \( \text{He} \) fraction in mixtures with \( \text{N}_2 \) or other heavier gases accelerates ion diffusion, which reduces the ion transmission.

**Figure 4.** Separation properties for major peaks of protonated Syntide 2 with \( z = 2 \)–4 in \( \text{H}_2/\text{N}_2 \) and \( \text{He}/\text{N}_2 \) mixtures: compensation field (top panel), peak widths (middle row), and resolving power (bottom row). The black lines are for the data\(^{24} \) in \( \text{He}/\text{N}_2 \), and circles are for \( \text{H}_2/\text{N}_2 \): filled for \( t = 0.2 \text{ s} \), blank (middle and bottom rows) for \( z = 3 \) at \( t = 0.15–0.16 \text{ s} \). The green line (middle row) shows the peak widths for \( z = 3 \) upon adjustment to \( t = 0.2 \text{ s} \) as explained above. The dashed lines (bottom panel) indicate the maximum \( R \) achieved\(^{36} \) for \( z = 2 \) and 3 with \( \text{He}/\text{N}_2 \) mixtures (using \( t = 0.5 \text{ s} \)).
through planar gaps and thus FAIMS sensitivity. The effect is greater with \( \text{H}_2 \) mixtures because of somewhat faster diffusion (Fundamentals section) and higher possible light gas fractions. For example, moving from 0 to 80% \( \text{H}_2 \) decreased the reserpine ion counts by \( \sim 3-4 \) times (at \( t = 0.2 \) s), and the losses for more mobile ions were steeper such that the signal often vanished by \( \sim 70\% \text{ H}_2 \) as we described. However, addition of \( \text{H}_2 \) must also affect the ESI desolvation efficiency (especially as the emitter voltage and geometry were varied at high \( \text{H}_2 \) content) and reduce ion transmission through the FAIMS inlet, FAIMS/MS junction, MS inlet capillary, and whole MS system flooded with \( \text{H}_2 \) at abnormal pressure near the boundary of operating envelope. Deconvoluting those phenomena is beyond the scope of this work, but redesigning the FAIMS unit as explained above and optimizing the MS platform for \( \text{H}_2 \) aspiration through raised pumping capacity and other changes is expected to improve the sensitivity of FAIMS/MS analyses employing either helium or hydrogen.

**CONCLUSIONS**

Replacing helium in \( \text{He}/\text{N}_2 \) and other FAIMS carrier gases with hydrogen relaxes the electrical breakdown constraint on the lighter gas fraction. This removes the risks to equipment, improves system stability, and substantially raises the resolving power while reducing the ion filtering time up to 4-fold. In particular, \( R \) values of 176 for dehydroreserpine (1+) and 185 for Syntide 2 (2+) demonstrated here (with statistical confirmation) are the highest reported for singly and doubly charged ions. The spectral profiles for various species in \( \text{H}_2/\text{N}_2 \) mixtures are close to those in \( \text{He}/\text{N}_2 \), and greater resolving power directly translates into resolution and peak capacity gains that rapidly increase at \( \text{H}_2 \) fractions above 50%. The \( \text{H}_2/\text{N}_2 \) mixtures suffer no electrical breakdown up to \( \sim 92\% \text{ H}_2 \) even at the maximum \( \text{DV} = 5.4 \) kV here, and separations improve up to \( \sim 90\% \text{ H}_2 \) (where \( E_C \) values for many species start dropping). However, the mechanical and electrical constraints of the present FAIMS design limited the \( \text{H}_2 \) content in \( \text{H}_2/\text{N}_2 \) for many analytes to \( \sim 55-80\% \), with lower values for more mobile ions. This circumstance reduced the benefit of \( \text{H}_2 \) for highest-mobility ions, such as 3+ and 4+ peptides. This problem can be addressed by optimizing the analyzers, and moving toward \( \sim 90\% \text{ H}_2 \) should further improve separation power and/or speed.

Media rich in \( \text{H}_2 \) can be useful for FAIMS alone and platforms involving other stages such as MS, conventional IMS, and/or various spectrometries. The acceleration of scanning should facilitate the integration of FAIMS with LC. Additionally, \( \text{H}_2 \) is cheaper than \( \text{He} \) and can be generated from water at little cost beyond a one-time expense of commercial equipment. The reduced operating cost and availability of \( \text{H}_2 \) on demand from compactly stored materials or ambient water should make high-resolution FAIMS devices more practical and portable.

The relatively low weight, power requirements, and ruggedness of IMS and FAIMS analyzers make them attractive for in situ characterization in space (e.g., of planetary atmospheres), and several such missions are contemplated. In this context, FAIMS using hydrogen-rich media may be ideal for probing exoplanet atmospheres with dominant \( \text{H}_2 \) fractions (e.g., \( \sim 87-96\% \) for Jupiter and Saturn).
